List of Acceptable Hybrids for 1980.....	42

Performance of Corn Hybrids in Alabama, 1979

Cliff G. Currier^{1/}

Corn hybrids are evaluated annually at 12 locations in the regular corn hybrid testing program of the Auburn University Agricultural Experiment Station. Preliminary tests also are conducted at 5 of the 12 locations. Entries in the regular tests have been tested one or more years and have performed well in the preliminary tests. Entries in preliminary tests are both experimental and newly released hybrids that have not been tested in the regular tests. If a hybrid is outstanding in the preliminary tests it is entered into the regular testing program the following year. White corn hybrid tests were initiated in 1979. Eight white corn hybrids were tested at one location in each region in 1979.

Rainfall distribution was fair to good depending upon location during the 1979 growing season. Excellent yields were obtained at Crossville, Fairhope, and the irrigated test at Headland. All locations, except the unirrigated test at Headland, had higher test averages than in 1978. Generally, yield reduction was due to the lack of adequate rainfall during the period of greatest need for moisture by the hybrids in the test. Data from Monroeville Experiment Field were not reported due to low and erratic yields. Data from Camp Hill were not reported due to large differences in plant population in the plots.

Locations of the tests, cultural practices, and average plant populations are shown in table 1. All hybrids at a location were treated the same. The experimental design was a randomized complete block with four replications. Row width was 36 to 42 inches depending on location. At Camp Hill, one-row plots 40 feet long were used. At all other locations, two-row plots were

^{1/}Research Associate, Department of Agronomy and Soils

used with row length varying from 18 to 30 feet depending on location. The target plant population for all tests was 20,000 plants per acre. The seeding rate was 23,000 seeds per acre at each location. The target plant population for the irrigated test at Headland was 26,000 plants per acre, with a seeding rate of 29,700 seeds per acre. Most locations achieved the target plant population.

Grain yields were adjusted to 15.5 percent moisture and converted to bushels (56 pounds) per acre. Stalks broken or leaning more than 45 degrees were considered lodged. Ear rot, earworn damage, size of grain, and luster of grain were used in rating grain quality. Height of ears was measured from the base of the ear to ground level. Husks were rated according to tightness and extension beyond the tip of the ear. Mid-silk data measured the number of days from planting until one half of the plants in the plot were showing silks.

Regional averages for 3, 2, and 1 years in northern Alabama are presented in tables 2, 3, and 4 respectively. Table 5 shows yields by location, and regional average yields for 1 to 5 years in northern Alabama. Similar data are given for central Alabama in tables 6-9, and for southern Alabama in tables 10-13. The irrigated hybrid test was moved from Camden to Headland in 1979. Yields from this test were excellent. Results of the irrigated corn hybrid test at Headland for 1 year are shown in table 14. In 1979, this test was sprinkler irrigated on May 28, June 1, 6, 12, and 18. Approximately 5 inches of irrigation water was applied over this period of time. Data from 1976, 1978, and 1979 tests at Marion Junction are given and should be used to assist in comparing hybrids grown in that area. Performance of corn hybrids at Marion Junction for 3, 2, and 1 years are given in tables 15, 16, and 17 respectively. Yields and other characteristics

of white corn hybrids grown at Crossville, E. V. Smith Research Center (near Shorter), and Headland are given in Table 18. Results of the preliminary tests are given in tables 20-22.

The corn hybrid tests are examined each year for viral and other disease symptoms by Dr. R.T. Gudauskas, Department of Botany, Plant Pathology, and Microbiology. When disease symptoms indicate that damage may occur, disease ratings are compiled and published in this report. An introduction and discussion of procedure and results are given. Virus infection data from the hybrid test at Camp Hill are given in table 19.

When comparing hybrids, small differences in yield may not be large enough to be considered real differences. To aid in determining real differences between hybrids a statistical procedure, analysis of variance, was performed on the data from each location. The L.S.D. (least significant difference) and C.V. (coefficient of variation) are given for yields at each location in 1979.

Since performance of hybrids may vary from year to year and location to location, long term averages from several locations are more reliable than 1-year averages when evaluating a hybrid from an area. Three-year results are considered sufficient to give a good indication of the relative performance of hybrids.

A composite rating system was used to determine the list of acceptable hybrids. The 3-year regional average grain yield of a hybrid was used as a base point. Then the composite score was obtained by subtracting weighted values for lodging, quality, and ear height from this yield. The value subtracted for each characteristic was proportional to the numerical values shown for the characteristics in tables 2, 6, and 10.

All acceptable hybrids are not equal in performance. Some are outstanding in one or more characteristics. Others may not be outstanding in any one characteristic, but possess a satisfactory combination of

characters. All information should be carefully considered when selecting a hybrid.

ACKNOWLEDGMENTS

Appreciation is expressed to the following people: W.H. Hearn and Mrs. Sally Bagwell, Research Data Analysis for the computation and summarization of the data in this report. R.T. Gudauskas, Department of Botany, Plant Pathology, and Microbiology for making the virus ratings and the virus infection tables in this report. Brenda Hood for typing this manuscript. The following cooperators in charge of their respective substations:

VIRAL DISEASE REACTIONS OF SOME HYBRIDS IN 1979

Robert T. Gudauskas

Department of Botany, Plant Pathology, and Microbiology

INTRODUCTION

The two most prevalent viral diseases of corn in Alabama are maize chlorotic dwarf (MCD) caused by the maize chlorotic dwarf virus (MCDV), and maize dwarf mosaic (MDM) caused by the maize dwarf mosaic virus (MDMV). Discovery of MDM in the State dates back to the early 1960's, while MCD has been recognized only since 1973. Both diseases probably occur throughout Alabama, however, they generally have been more prevalent and damaging in the northern two-thirds of the State.

Symptoms of the two diseases are similar in appearance and sometimes difficult to distinguish. Generally, affected plants are chlorotic or discolored and may be stunted. Leaves of MDM-diseased plants show an irregular, light and dark green mosaic or mottle; the initial symptom of MCD is a fine, chlorotic streaking over smallest veins.

The causal viruses are spread by feeding activities of insects. MCDV is transmitted by certain leafhoppers and MDMV is carried by some aphids. Both viruses have similar host ranges among a variety of wild and cultivated grasses. Johnsongrass is an important overseason or reservoir host for the viruses, and MCD and MDM incidence and damage usually are high in corn fields that are heavily infested with johnsongrass.

Use of resistant or tolerant corn hybrids presently is the most practical control for MCD and MDM. Commercial and experimental hybrids and inbred lines are evaluated yearly to identify resistant hybrids of promising

sources of resistance to the diseases. Results of evaluations of some commercial hybrids during 1979 are summarized in this report.

PROCEDURE

Viral disease ratings were made on entries in the corn hybrid test at the Piedmont Substation, Camp Hill. Plants showing symptoms of MCD and/or MDM were counted and data are reported as percent incidence of the diseases for each hybrid.

RESULTS

Evaluations for viral diseases in the hybrid test on the Piedmont Substation are given in table 19. Tests on the Black Belt, Tennessee Valley, Sand Mountain, and Upper Coastal substations were also examined but disease incidence was insignificant.

With two exceptions, MCD and MDM were found in every hybrid in the Piedmont test. Average incidents of MCD within all hybrids was 7.2% as compared to 16.7% for MDM. Occurrence of both diseases in the same plant was frequently observed.

Hybrids showing relatively greater resistance or tolerance were apparent. Under conditions of higher or lower incidence of viral diseases many hybrids would be more or less susceptible but should retain their relative ranking. When selecting a hybrid, viral disease reactions should be taken into account for areas where the diseases occur, along with consideration of yield and other characteristics given elsewhere in this report.

ACCEPTABLE HYBRIDS FOR 1980

All of the acceptable hybrids are not equal in performance. It is suggested that this report be carefully studied before choosing a hybrid. Hybrids are listed in descending order of their composite rating. For relative maturity information for these hybrids, use the number of days to midsilk, found in tables 4, 8, and 12. All hybrids have yellow grain except the white hybrids indicated by a (W). All composite ratings are based on 1977-79 regional averages, found in tables 2, 6, and 10.
